## Abstract

Guaranteeing stable electricity demand forecasting is paramount for the conservation of material resources. However, because electricity consumption data are often made up of complex and unstable series, it is very hard for a simple single method to always obtain accurate predictions. To improve electricity demand forecasting robustness and accuracy, a hybrid empirical mode decomposition and state space model are proposed, for which the empirical mode decomposition is applied to decompose the total time series (noise filtering), and the state space model is employed to forecast every sub-series (feature extraction), with the state space model parameters being optimized using maximum likelihood via a Kalman filter. Compared with autoregressive integrated moving average model and artificial neural networks, the proposed model had more stable and accurate forecasting. This method could be broadly applied to not only forecast electricity demand, being a key step for developing electricity generation plans and formulating energy policy, but also forecast any similar time series data with noise and substantive latent features, making a new step toward solving such a problem.

## Introduction

As a long-term important hot issue, electricity demand forecasting research can date back to Heinemann et al.<sup>1</sup> Hobbs et al.<sup>2</sup> stated that with a reduction of 1% in the forecasting mean absolute percentage error (MAPE), 10,000 MW of electricity energy can be saved, which means power grid planning, investment, and transactions are based on accurate electricity demand forecasting, an accurate forecasting model could save up to \$1.6 million a year.

Electricity forecast horizons can be short term from an hour or a week, medium term from a week to a year, or long term for over a year.<sup>3,4</sup> Medium-term electricity demand forecasting and especially monthly forecasting is a critical index for many business and government decision-making processes,<sup>5</sup> as it is designed to maintain a balance between supply and demand.<sup>6</sup>

Due to the complexity and instability of electricity consumption data, no one best individual method has been found to always perform well. However, as ensemble learning and hybrid methods seek to obtain better forecasting performance by strategically combining multiple algorithms,<sup>7</sup> this paper develops a hybrid monthly electricity demand forecasting model based on empirical mode decomposition (EMD) and a state space model (SSM), which will provide a new step for solving time series data with noise and substantive latent features. The EMD as a noise filter is applied to decompose the total time series, and the SSM is employed for the feature extraction and forecasting of each every sub-series; with the SSM being optimized using maximum likelihood Kalman filter.

The remainder of this paper is organized as follows. The following section gives a brief literature review, the third section introduces the proposed method, the fourth section reviews the data and forecasting results, and final section concludes the paper.

## Literature review

Modeling and forecasting electricity demand is an indispensable part of demand side management.<sup>8</sup> Even though researchers have been developing and enhancing many electricity demand forecast models, they have been modeled around two main forecasting methods, individual forecasting and hybrid forecasting.

Individual forecasting models such as time series analysis and machine learning models have been the most widely used to date. Time series analysis seeks to extract meaningful statistics and other characteristics from the time series data by analyzing the data itself,<sup>9</sup> and therefore time series models have been widely used for electricity load forecasting using linear regression,<sup>10</sup> seasonal autoregressive,<sup>11</sup> autoregressive integrated moving average (ARIMA),<sup>12</sup> threshold autoregressive,<sup>13</sup> Kalman filtering,<sup>14</sup> and seasonal autoregressive integrated moving average methods.<sup>15</sup> As it does not account for the exogenous variables, time series analysis models only require the consumption data to be complete for the forecasting. Machine learning models, such as artificial neural networks (ANNs),<sup>16</sup> support vector machines,<sup>17</sup> Gaussian process,<sup>18</sup> grey forecasting model,<sup>19</sup> Markov model,<sup>20</sup> and ensemble learning methods<sup>21</sup> have also been employed to forecast electricity demand. Although machine learning models have proven to be very accurate, these models are unsuitable for analyzing electricity demand as they are unable to provide any insights into the causes of structural changes.<sup>22</sup>

However, because of the many factors that affect electricity demand as well as the non-stationary nature of electricity consumption data, using only one individual model may not

produce good results.<sup>23</sup> To address this challenge, highly accurate forecasting models and hybrid technologies have been considered to improve model performance. Hybrid models, which are an integration of different models, can improve the forecasting accuracy. When models are combined, they can capture the different electricity consumption features and overcome the defects in the individual models.<sup>24</sup> Hybrid models also have better performance than individual models because of bias-variance decomposition and strength-correlation.<sup>9</sup> Therefore, hybrid models have generally proven to be superior to single models. Hybrid electricity load forecasting models can be classified into three main categories.

1. In the first category models, the electricity demand is forecast separately by the different models, after which the weight of each model is calculated using a suitable method. The final forecasting value is determined by adding each model's forecasting value multiplied by its weight. Nowotarski et al.<sup>25</sup> investigate the performance of combining so-called sister load forecasts which share similar model structure but are built based on different variable selection processes. Besides, Xiao et al.<sup>26</sup> used a multi-objective flower pollination algorithm to optimize the weights of single models that included several ANNs.
2. The second model category supposes that there is a linear part and a nonlinear part. The data are forecast using the linear model and the residuals checked for a nonlinear pattern, after which the residuals are forecast using a nonlinear model and vice versa. The model's final forecast is determined from the sum of the linear and nonlinear model results. Barak and Sadegh<sup>27</sup> combined ARIMA and an adaptive neuro fuzzy inference system and found that they were good in linear and nonlinear structural performances. Moreover, Wang et al.<sup>28,29</sup> use the linear ARIMA to correct nonlinear metabolic grey model forecasting residuals to improve forecasting accuracy.
3. The third category model decomposes the electricity consumption data into several sub-series, after which each sub-series is forecast using a suitable model. The final forecast results are the sum of each of the sub-series' forecasting results. Popular decomposition technologies are EMD, wavelet transforms, and Fourier transformation. Li et al.<sup>30</sup> used wavelet transformation to decompose original electricity consumption data into several sub-series, after which each sub-series was forecast by an extreme learning machine combined with partial least squares regression, and Zhang et al.<sup>24</sup> proposed a hybrid model based on improved EMD, ARIMA, and a wavelet neural network that had been optimized using a fruit fly optimization algorithm.

While EMD, Fourier, and wavelets are all used to decompose signals, EMD is fundamentally different from the other two. EMD makes no assumptions a priori about the composition of the signal. Rather, it uses spline interpolation between maxima and minima to successively trace out "intrinsic mode functions" (IMFs). Since it makes no assumptions about signal, the results might be more meaningful. Also, since the IMFs can change over time, EMD makes no assumptions about the stationarity of the signal (or the signal components) and is therefore better suited to nonlinear signals than either Fourier or wavelets. This makes EMD particularly attractive when analyzing signals from complex systems, for instance in electricity demand analysis. To increase the efficiency of decomposition, EMD was used by many researchers.<sup>31–33</sup> Qiu et al.<sup>9</sup> used EMD to decompose the electricity load into some detail parts and an approximate part. Then the deep belief network model was used for forecasting. Xiong et al.<sup>34</sup> used EMD to increase decomposition efficiency and introduced an EMD-based support vector regression modeling framework.

Unlike most studies, this paper focused on the basic characteristics of electricity consumption data such as trend, season, cycle, and random effect. In addition, every IMF and residue component is forecast by SSM next because a simpler model can make less cost. Therefore, a simpler calculation and a higher accuracy forecasting ensemble are constructed to forecast electricity demand. In addition, one of the advantages of SSMs is that the individually created models (sub-models or components) can be easily incorporated into a single model.<sup>22</sup> Consequently, SSMs were developed to assess national electricity demand in France.<sup>35</sup> Therefore, to capture the different characteristics and to overcome the shortcomings of a single model, this paper presents a hybrid combined EMD and SSM model to forecast monthly electricity demand, which has the following advantages.

1. To more accurately and effectively extract the electricity demand characteristics, the EMD is used to reduce information loss, which has rarely been discussed in electricity demand decomposition research.
2. Based on its specific features and fit characteristics in the original electricity consumption, each sub-series decomposed from the original electricity consumption is forecast using a suitable SSM.

## Methodology

Because of the specific monthly electricity consumption data characteristics, this section presents the key components for the proposed forecasting method (EMD–SSM). The EMD extraction process first deals with the noise filtering, after which the SSM model combined with the EMD interpolates and extrapolates the latent components such as the trends, seasonal effects, and irregularities.

### Noise filtering (EMD)

Known as the Hilbert–Huang transformation,<sup>36</sup> EMD, an empirical approach to obtaining instantaneous frequency data from non-stationary and nonlinear data sets, decomposes a signal into several IMFs and a residue.

As it is influenced by several factors, electricity consumption is a random, non-stationary process composed of thousands of individual components, with the data having trend, season, cycle, and random effect characteristics; therefore, the EMD algorithm can be very effective for noise filtering.

An IMF is a function that has only one extreme between zero crossings and a mean value of zero. The shifting process EMD uses to decompose the signal into IMFs is described in the following:

1. For a time series  $x(t)$ , let  $m_1$  be the mean of its upper and lower envelopes as determined by a cubic-spline interpolation of the local maxima and minima.
2. The first component  $h_1$  is computed by subtracting the mean from the original time series:  $h_1 = x(t) - m_1$ .
3. In the second shift process,  $h_1$  is treated as the data, and  $m_{11}$  is the mean of  $h_1$ 's upper and lower envelopes:  $h_{11} = h_1 - m_{11}$ .
4. This shifting procedure is repeated  $k$  times until one of the following stop criterion is satisfied: (i)  $m_{1k}$  approaches zero, (ii) the number of zero crossings and extrema for  $h_{1k}$

differs at most by one, or (iii) the predefined maximum iteration is reached.  $h_{1k}$  can be treated as an IMF in this case and computed by:  $h_{1k} = h_{1(k-1)} - m_{1k}$ .

5. Then it is designated as  $c_1 = h_{1k}$ , the first IMF component from the data, which contains the shortest signal period component, which is then separated from the rest of the data:  $x(t) - c_1 = r_1$ . This procedure is repeated for  $r_j$ :  $r_1 - c_2 = r_2, \dots, r_{n-1} - c_n = r_n$ .

As a result, the original time series signal is decomposed into a set of functions:  $x(t) = \sum_{i=1}^n (c_i) + r_n$ , where the number of functions  $n$  in the set depends on the original signal.

### Feature extraction (SSM)

SSM, also known as Kalman filtering, was first introduced by Kalman.<sup>37</sup> State space models consist of two equations to simultaneously account for two variation distinct sources: the state equation (latent process) deals with the process uncertainty caused by the unobserved factors, and the observation model incorporates the effect of the error caused by the mis-measurement of outcomes. The general form for a state space model is as follows

$$\begin{cases} \text{Observation equation :} & Y_t = Z_t \alpha_t + \epsilon_t, \\ \text{State transition equation :} & \alpha_{t+1} = T_t \alpha_t + \eta_{t+1} \end{cases} \quad (1)$$

where  $n \times 1$  vector  $\alpha_t$  is the state vector, denoting the state at time  $t$ ; and  $k \times 1$  vector  $y_t$  is the observations at time  $t$ ; and  $\epsilon_t$  and  $\eta_t$  are the observation and state noises, which are respectively drawn from Gaussian distributions with zero means, variances of  $R_t$  and  $Q_t$ , and  $S_t$  covariances. The  $n \times n$  matrix  $T_t$  called the transition matrix and the  $k \times n$  matrix  $Z_t$  called the output matrix in equation (1) are referred to as the system matrices with appropriate dimensions.

It is well known in the time series analysis that unobserved components model has been proven to be very effective.<sup>38–40</sup> And a very successful and widely accepted unobserved components model comprises trend, cycles, seasonal, and irregular components.<sup>41</sup> Hereafter, the SSM model is employed to forecast each sub-series, the general form for which is

$$y_t = \mu_t + \gamma_t + c_t + \epsilon_t$$

where  $y_t$  is the observation vector at time  $t$ ,  $\mu_t$  is the trend component,  $\gamma_t$  is the seasonal component,  $c_t$  is the cycle component, and  $\epsilon_t$  is an irregular component. The modeling details for these components are described in the following.

The trend component is a dynamic regression model extension that includes an intercept and linear time-trend and is given as

$$\begin{aligned} \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_{t-1}, \\ \beta_t &= \beta_{t-1} + \zeta_{t-1} \end{aligned}$$

where the level is a generalization of an intercept term that can dynamically vary across time, and the trend is a generalization of the time-trend so that the slope can dynamically vary across time:  $\eta_t \sim N(0, \sigma_\eta^2)$  and  $\zeta_t \sim N(0, \sigma_\zeta^2)$ .

The seasonal component is modeled as

$$\gamma_t = -\sum_{j=1}^{s-1} \gamma_{t+1-j} + \omega_t$$

where  $s$  is the number of seasons (12 in monthly data), and  $\omega_t \sim N(0, \sigma_\omega^2)$ . This component results in one parameter to be selected via maximum likelihood:  $\sigma_\omega^2$  and one parameter to be chosen, the number of seasons  $s$ .

The cyclical component is intended to capture the cyclical effects at time frames much longer than those captured by a seasonal component

$$\begin{aligned} c_{t+1} &= \rho_c(\tilde{c}_t \cos \lambda_c t + \tilde{c}_t^* \sin \lambda_c t) + \tilde{\omega}_t, \\ c_{t+1}^* &= \rho_c(-\tilde{c}_t \sin \lambda_c t + \tilde{c}_t^* \cos \lambda_c t) + \tilde{\omega}_t^* \end{aligned}$$

where  $c_t$  and  $c_t^*$  are independent, zero mean, Gaussian disturbances with variance  $\sigma_\omega^2$ ,  $\omega_t, \tilde{\omega}_t$  iid  $N(0, \sigma_\omega^2)$ , damping factor  $\rho_c$  can be any value in the interval  $(0, 1)$ , including one but excluding zero and parameter  $\lambda_c$  (the frequency of the cycle) is an additional parameter to be estimated using maximum likelihood estimation.

An autoregressive component (that is often used as a replacement for the white noise irregular term)

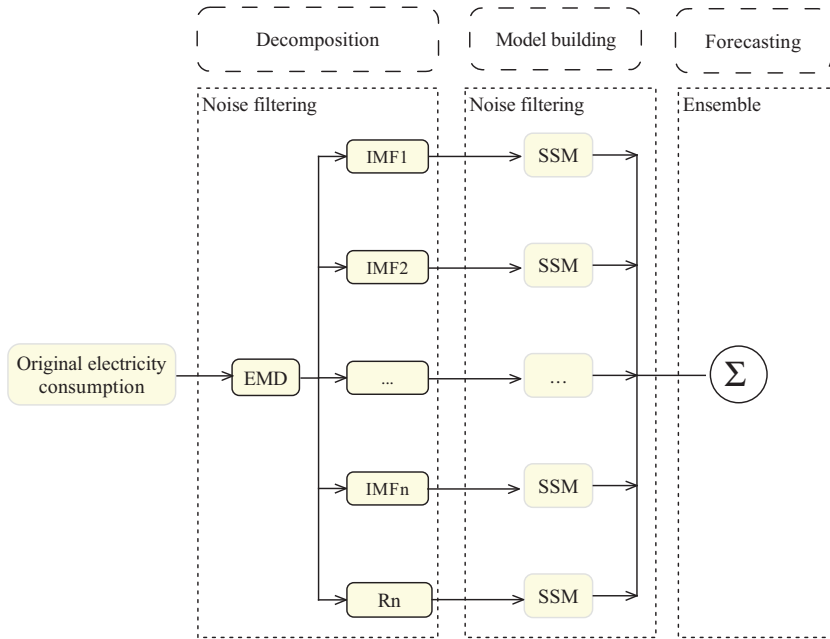

$$\varepsilon_t = \rho(L)\varepsilon_{t-1} + \epsilon_t, \quad \epsilon_t \sim N(0, \sigma_\epsilon^2)$$

In summary, the SSM can be written as follows

$$\begin{aligned} \text{Observation equation : } y_t &= \mu_t + \gamma_t + c_t + \varepsilon_t, \\ \text{Transition equation : } \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_{t-1}, \\ \beta_t &= \beta_{t-1} + \zeta_{t-1}, \\ \gamma_t &= -\sum_{j=1}^{s-1} \gamma_{t+1-j} + \omega_t, \\ c_{t+1} &= \rho_c(\tilde{c}_t \cos \lambda_c t + \tilde{c}_t^* \sin \lambda_c t) + \tilde{\omega}_t, \\ c_{t+1}^* &= \rho_c(-\tilde{c}_t \sin \lambda_c t + \tilde{c}_t^* \cos \lambda_c t) + \tilde{\omega}_t^*, \\ \varepsilon_t &= \rho(L)\varepsilon_{t-1} + \epsilon_t, \quad \epsilon_t \sim N(0, \sigma_\epsilon^2) \end{aligned}$$

### EMD-based SSM model

The proposed hybrid EMD and SSM electricity demand forecasting model decomposes the electricity consumption data into several IMFs and one residue using the EMD method, after which the SSM model is applied to each IMF and the residue. When the forecasting for

**Figure 1.** Schematic diagram of the proposed EMD-SSM method.

all sub-series is the complete, the forecasting results are aggregated by simple addition to obtain the final forecasting. Figure 1 shows the overall schematic for this ensemble method:

1. The time series data are decomposed using EMD into several IMFs and one residue.
2. For each IMF and the residue, one training data are constructed as the SSM input.
3. The SSM is then trained to obtain the forecast results for each of the extracted IMFs and the residue.
4. All forecast results are added to formulate the ensemble output for the time series.

### Error measurement

As suggested by Taylor<sup>42</sup> and Shaikh and Ji,<sup>43</sup> forecast model performance can be evaluated using the absolute relative error (ARE), the root mean square error (RMSE), the mean absolute error (MAE), and the MAPE, each of which is defined as follows

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |y_i - \hat{y}_i|, \quad \text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (\hat{y}_i - y_i)^2}$$

$$\text{ARE} = \left| \frac{\hat{y}_i - y_i}{y_i} \right|, \quad \text{MAPE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{\hat{y}_i - y_i}{y_i} \right|$$

where  $\hat{y}_i$  is the forecast value of the corresponding  $y_i$ , and  $n$  is the number of data points in the testing time series.

## Results and discussion

### *Data handling*

This study was based on electricity consumption data from January 2007 to October 2010 in Sichuan Province, China. The data sets were generated by the Electricity Saving Association, which is the major source of power data in the province and covers almost all sectors of the economy. Total electricity consumption was composed of residential and nonresidential (industrial, transportation, manufacturing, and information service) electricity demand consumption. To make the results more convincing, all electricity consumption variables: that is, the total electricity consumption and its components were forecast. For a fair comparison analysis, each consecutive three months in 2010 were used as test set and the 36 months before the test month were used as training set. The specific data divisions are shown in Table 1.

### *Model adaptability*

Figure 2 shows that mixed with various signals (trend, season and cycle), the original data seem to be volatile and unstable. First, EMD is used to decompose original electricity consumption for noisy filtering. Figure 3 shows the decomposition results by EMD for training set 1. After decomposition, every sub-series is stable with different feathers; for example, cycle in 3decomposition and 4decomposition, trend in 5decomposition. SSM then is used to fit every sub-series for feature extraction. Finally, the forecast model could be obtained by adding all sub-models. The adaptability of the proposed method for total electricity consumption is shown in Figure 4 and Table 2. The adopted modeling approaches were found to be a good fit for the training sets. Figure 4 shows the results of EMD–SSM for the three-period-ahead total demand forecasting for training sets 1–4. Satisfactory results were obtained using the proposed method as the shape of the forecast curves was very similar to the shape of the actual curves. Starting at zero, the fitting curves were poor for the first few points; therefore, all measurements (in Table 2) were calculated using the remaining 26 consumption data. Table 2 shows the results for the three error measurements for total electricity consumption in the training sets. As all MAPEs were lower than 0.03 and the MAEs and RMSEs were also low, the proposed method was in a good fit for the total power consumption in the training sets.

**Figure 2.** Total electricity consumption from January 2007 to December 2010.

To verify the adaptability of EMD–SSM, one-period-ahead forecasting was conducted for different electricity variables using 10 test sets (Table 3). As shown, nearly 100% of the ARE outputs for the total power demand forecasting were lower than 0.1 and 70% were lower than 0.05. For the other electricity variables, most ARE outputs were lower than 5% or around 5% and only several were higher than 0.1, all of which indicated that the EMD–SSM was able to achieve precise and stable forecasting.

The other statistical results in Table 4 further illustrate the performance of the proposed model. The proposed model performed well for the different electricity variables as there were low average values and ARE variances. The maximum AREs were lower than 0.1 for the total, industry, and transportation power consumption, indicating satisfactory results. However, the results were unsatisfactory for residential, manufacturing and information service electricity demand forecasting as the maximum AREs were respectively 0.144, 0.147, and 0.165. These results can be explained by the amount of training data available for each electricity variable; that is, there was a large amount of training data for the total, industry, and transportation power consumption, but significantly less for the residential, manufacturing, and information service power consumption. Despite these results, according to Williams,<sup>44</sup> actual power generation must be able to accommodate up to a 15% increase in extra demand at any time, which means that even in the worst situation, the proposed method is in the highly accurate and stable forecast range.

### *Comparison analysis with benchmark methods*

Well known and accurate, benchmark methods are very useful when seeking to understand relative accuracy and can assist in identifying the weaker areas in proposed models.<sup>22</sup> Over the years, various forecasting models have been developed in literature, of which the ARIMA and ANN are widely popular. ARIMA models are well known for their notable forecasting accuracy and flexibility in representing several different types of time series.<sup>45</sup> Meanwhile, ANN is proved to be suitable for complex nonlinear time series modeling.<sup>46</sup> To further substantiate EMD–SSM the forecasting results, comparison analyses with three benchmark methods: ARIMA, ANN-1 (with 1 hidden layer), and ANN-2 (with 2 hidden layer) were conducted.

AREs: absolute relative errors; EMD: empirical mode decomposition; SSM: state space model.

**Table 4.** Statistical ARE values for the different electricity variables (one-period-ahead).

Electricity variable	Average value	Variance	Minimum	Maximum
Total	0.046	0.0010	0.008	0.105
Nonresidential	0.044	0.0010	0.001	0.125
Residential	0.070	0.0018	0.011	0.144
Industry	0.054	0.0011	0.007	0.100
Transportation	0.032	0.0005	0.004	0.076
Manufacturing	0.068	0.0022	0.016	0.147
Information service	0.066	0.0025	0.009	0.165

ARE: absolute relative error.

The basic steps for the ARIMA are as follows: first, the non-stationary series is transformed to a stationary series using differencing, after which  $p$  (the order of the autoregressive part) and  $q$  (the order of the moving-average process) are determined using autocorrelation function and partial autocorrelation function, and the optimal model determined by checking for white noise residuals. The ANN models use the six-month electricity consumption prior to the three months to be forecast as the input data and have six input neurons, 12 hidden

ANN: artificial neural network; AREs: absolute relative errors; ARIMA: autoregressive integrated moving average; EMD: empirical mode decomposition; SSM: state space model.

neurons for each hidden layer, and three output neurons. A rectified linear unit activation function is used as the hidden layer activation function, a linear function is used in the output layer, and adaptive moment estimation is used as the learning algorithm.

To verify the effectiveness of the proposed model, three electricity demand periods were forecast. Every three months in 2010 were used as the test set and the 36 months before the test set were used as the training set. Table 5 presents the AREs for every month for the test set. As can be seen, the same training set is used in the same column of Table 5. Table 6 shows the other evaluation criteria for the three months for every test set using the corresponding training set.

As can be seen in Table 5, the forecast accuracy of the proposed model was higher than the comparison models. The ARE for the EMD–SSM was in the range 0.0014–0.1428 which was the narrowest of the four methods. Further, no matter what the forecast period, the ARE averages for the proposed method were the lowest (0.455, 0.0608 and 0.0608, respectively). In addition, as shown in Table 6, the EMD–SSM achieved the lowest MAPE, MAE, and RMSE for most of the test sets, which indicated that the hybrid model had the best stability. Both Tables 5 and 6 demonstrate that the proposed model had more accurate and stable results compared to the other models.

To further illustrate the effectiveness of the EMD–SSM, Table 7 summarizes the number of times the four methods ranked 1, 2, 3 or 4. The EMD–SSM was ranked 1 three times, ranked 2 four times, ranked 3 once, and was never ranked 4, again demonstrating the superiority of the proposed model.

The comparison of the descriptive statistical values for the different evaluation criterions found that the average values for the MAPE, MAE, and RMSE obtained using the proposed method were lower than the comparative models (Table 8). The proposed model accuracy was able to attain an operational level and outperformed the benchmark methods. The average

**Figure 5.** Boxplot for the MAPE distribution.

To verify the above, boxplots were drawn to show the MAPE distribution and are presented in Figure 5. Even though there were no significant differences between the benchmarks and the proposed model, the boxplots show that the proposed method performed better than the ARIMA and the ANNs because it achieved the lowest  $Q_{25}$  (25th percentile), median, and  $Q_{75}$  (75th percentile) and had the narrowest inner fence. Table 8 and Figure 5 demonstrate that the proposed model was able to provide more accurate and more stable results than the benchmark models.

To present the advantages of the proposed model with a deep analysis, Table 6 shows that the ANN-2 achieved the highest MAPE, MAE, and RMSE for most of the test sets. Moreover, ANN-2 was ranked four times in the four models as shown in Table 7. Also, Figure 5 shows that the ANN-2 obtained the stable but very bad results because of the

higher MAPE means, median and the minimum. These all illustrate that the ANN-2 is not suitable for this data set, which may be caused by overfitting or local minimum. Meanwhile, all results show that ANN-1 and ARIMA are also disappointing compared with the EMD–SSM. In addition, a further analysis using original data indicated that when data set size used to train the simple ANN was altered, there was an obvious impact on its generalization ability.<sup>47,48</sup> Therefore, even though there was a relatively small 36-month training set for each forecasting process, the proposed model still performed well, which indicated that the EMD–SSM could perform well on smaller data sets.

## Conclusion

For monthly electricity demand forecasting, a long-term important hot issue, this paper proposed a hybrid model, formulating an EMD-based SSM. (1) EMD was introduced for noise filtering in the original electricity consumption, from which several IMFs with one residue were obtained. After decomposition, every IMF shows obvious features, such as trends, cycles, and seasoning. (2) The SSM was used to extract the latent features of each IMFs as well as the residue. (3) The electricity demand forecasting was then obtained through ensemble learning. Electricity consumption data from the Electricity Saving Association of Sichuan Province in China were used to demonstrate the performance of the proposed model, with all results indicating that the proposed model was able to improve electricity demand forecasting accuracy compared to the ARIMA and ANN models.

Based on the common forecast model performance evaluation together with statistical comparison analysis, four facts clearly emerged from the results: (1) EMD can effectively reduce original electricity consumption data noise; (2) the SSM can flexibly extract the time series features and fit well with the decomposed components; (3) by harnessing the advantages of both the EMD and SSM, the hybrid model is able to capture the different features associated with electricity demand; and (4) the EMD–SSM also performs well on small data sets. The EMD–SSM method was firstly proposed by combining the advantages of EMD and SSM, and the results indicated that the ensemble-learning method is valid and achieves good performance.

Obviously, although this paper was focused on the forecasting of monthly series data sets, the methods shown here could also be applied to quarterly or yearly data. Basically, this paper provided a new step for any time series data with noise and substantive latent features, within electricity demand forecasting or in other similar forecast fields. And the approach applied in this work can be implemented for other provinces or countries to make accurate predictions for the future. The results stated that the proposed methods, dealing with noise filtering and feature extracting, have the potential to generate growth in an important new forecast sub-area that may be small now but is expected to grow. For example, to further improve the forecast power, different models such as machine learning methods could be used on decomposed series.
